Many QTL mapping methods have been developed in the past two decades. Statistically, the best method should have a high detection power but a low false discovery rate (FDR). Power and FDR cannot be derived theoretically for most QTL mapping methods, but they can be properly evaluated using computer simulations. In this paper, we used four genetic models (two for independent loci and two for linked loci) to illustrate power and FDR estimation for interval mapping (IM) and inclusive composite interval mapping (ICIM). For each model, we simulated 1000 populations each of 200 doubled haploids. A support interval (SI) was first defined to indicate to which predefined QTL the significant QTL belonged. Power was calculated by counting the number of simulation runs with significant peaks higher than the logarithm of odds (LOD) threshold in the SI. Quantitative trait loci not identified in any SIs were viewed as false positives. The FDR is the rate at which QTLs are identified as significant when they are actually non-significant. Simulation results allowed us to estimate power and FDR of IM and ICIM for two independent and two linkage genetic models. Our estimates allowed us to readily compare the efficiencies of different statistical methods for QTL mapping, including the ability to separate linkage, under a wide range of genetic models. We used IM and ICIM as examples of how to estimate power and FDR, but the principles shown in this paper can be used for power analysis and comparison of any other QTL mapping methods, especially those based on interval tests.

false discovery rate (FDR), inclusive composite interval mapping (ICIM), interval mapping (IM), power simulation

Quantitative trait locus (QTL) mapping has become routine for genetic studies of complex traits in plants, animals, and humans. Interval mapping (IM) has been viewed as a milestone in QTL mapping methods; IM uses a likelihood ratio test for the existence of QTLs based on maximum likelihood parameter estimation [1]. However, conventional IM cannot properly separate linked QTLs [2,3], and its power of detection is low, because of the lack of a background control. Composite interval mapping (CIM), proposed by Zeng [4], is one of the most commonly used methods, but CIM can result in biased mapping because it simultaneously estimates QTLs and background effects [5]. Inclusive composite interval mapping (ICIM) is a critical step forward

that highlights the importance of model selection and interval testing in QTL linkage mapping, and is able to separate linked QTLs through a two-step mapping strategy [5–8]. In addition, ICIM can be readily extended to epistasis mapping and QTL mapping in multi-parental populations [9–11].

There are many other QTL mapping methods in addition to IM, CIM, and ICIM [5,12–14]. To appropriately evaluate the efficiency of these methods, we need to compare the true QTL positions and effects with their estimate and calculate the statistical power and false discovery rate (FDR). As with any statistical test, two types of error, Type I and Type II, can occur in QTL mapping [5,8,11]. (1) A Type I error is a false positive, in which a segregating QTL is detected when in fact it is not present. (2) A Type II error is a false negative, in which a QTL is not detected when it actually exists.

*Corresponding authors (email: wangjk@caas.net.cn; jkwang@cgia.org)

Type I error can be controlled by choosing proper critical values, whereas Type II error is determined by the experiment design and the size of the QTL effect. Statistical power is the probability that the null hypothesis is rejected when it is indeed false. In other words, if β is the probability of Type II error, the power equals $1-\beta$. In QTL mapping, power indicates the probability that a real QTL is detected and is therefore the most important indicator of the method's efficiency. The FDR offers an intuitive balance between false and true positives [15]. The FDR is defined by the rate at which significant features are truly null.

The asymptotical properties of test statistics used in most QTL mapping methods are hardly known, therefore the statistical power and the FDR cannot be estimated theoretically [8,16]. When using actual mapping populations, the true QTL positions and effects are usually unknown. Another problem with using real data to compare methods is that the parameter ranges are usually limited by experimental conditions, genetic architectures, and species. Collecting real data occupying the full range of parameter spaces is usually im-

possible.

Monte Carlo computer simulation is often used in physical and mathematical systems when computing an exact result with a deterministic algorithm is infeasible or impossible. It provides an efficient way to calculate the power and FDR of different QTL mapping methods to evaluate and compare their efficiencies. Our objective in this paper was to illustrate how detection power and FDR can be estimated in simulated populations under various genetic models, using two QTL mapping methods (i.e., IM and ICIM) as examples.

1 Materials and methods

1.1 Genetic model

In our simulation studies, we considered four QTLs with different additive effects affecting a quantitative trait and a genome of six chromosomes (Table 1). Each chromosome was 120 cM in length with 13 evenly-distributed markers.

Table 1 Characteristics of four genetic models for four QTLs used to estimate the power and false discovery rate of interval mapping and inclusive composite interval mapping

Model	Chromosome	Position (cM)	Additive effect	PVE (%) ^{a)}
Independent I				
Q1	1	35	0.316	5.0
Q2	2	35	0.447	10.0

Genetic variance	0.465			
Error variance	1.000			
Heritability	0.317			

a) PVE, phenotypic variance explained by each QTL.

Each marker interval was 10 cM. Two independent models (Independents I and II) and two linkage models (Linkages I and II) were defined. When there was no linkage, the four QTLs were located on the first four chromosomes at position 35 cM. Each independent model represented a different scenario of QTL effects. In Independent I, the four QTLs had additive effects 0.316, 0.447, 0.548, and 0.633, respectively, indicating that one parent had the four favorable alleles, and the other parent had the four non-favorable alleles. When error variance was 1.00, they explained 5%, 10%, 15%, and 20% of phenotypic variance, respectively. In Independent II, the four QTLs had additive effects 0.316, -0.447, 0.548, and -0.633, respectively, indicating that one parent had the favorable alleles for two loci, and the other parent had the favorable alleles for the other two loci. They explained the same amount of phenotypic variance as in Independent I. The total genetic variance is sum of individual QTL variances, i.e., $V_G = \sum_{i=1}^4 a_i^2$, where a_i is the additive effect of the i th QTL. When the error variance was fixed at 1 in the independent models, genetic variance was 1 and heritability was 0.5.

For the two linkage models, Q1 and Q2 were located at 35 and 65 cM on chromosome 1, and Q3 and Q4 were located at 35 and 65 cM on chromosome 2 (Table 1). In Linkage I, the QTLs had the same effects as in Independent I, representing coupling linkage. In Linkage II, the QTLs had the same effects as in Independent II, representing repulsion linkage. If r is the recombination frequency between two linked QTLs having a genetic distance of d cM,

$r = \frac{1}{2}(1 - e^{-d/50})$ in Haldane's mapping function. The total genetic variance is

$$V_G = \sum_{i=1}^4 a_i^2 + 2(1 - r_{12})a_1a_2 + 2(1 - r_{34})a_3a_4,$$

where a_i is the additive effect of the i th QTL, r_{12} is the recombination frequency between Q1 and Q2, and r_{34} is the recombination frequency between Q3 and Q4. When the error variance was fixed at 1.00 in the linkage models, genetic variance was 1.535 for Linkage I and 0.465 for Linkage II, resulting in heritabilities of 0.606 and 0.317, respectively.

1.2 Simulation of genetic populations and their QTL mapping

One thousand doubled haploid populations, each of size 200, were simulated for each model, and QTL mapping was completed using the QTL IciMapping software package, which is freely available from <http://www.isbreeding.net>. IM and ICIM were used on each simulated population. In the first step of ICIM, marker selection was conducted through stepwise regression by considering all marker information simultaneously. The two probabilities for enter-

ing and removing variables in the first step were set at 0.001 and 0.002, respectively. Phenotypic values were then adjusted for all markers retained in the regression equation, except for the two markers flanking the current mapping interval. In the second step, the adjusted phenotypic values are used in one-dimensional scanning. The logarithm of odds (LOD) threshold was set at 2.5 for IM and ICIM.

1.3 Estimation of statistical power and false discovery rate

Both IM and ICIM are based on an interval test, which is not a point estimation procedure [5]. The LOD score is the test statistic used in IM and ICIM and is calculated for each position in the genome through one-dimensional scanning. Example LOD profiles from IM and ICIM in five simulated populations are shown in Figures 1 and 2 for the independent and linkage models, respectively. QTLs are identified at the peaks on the LOD profiles. One QTL was unlikely to be located exactly at the predefined position in each simulated population. The multiple non-independent and non-point tests complicate the calculation of power, even though simulation. In particular, when QTLs are closely linked, determining which putative QTL the LOD peak belongs to is difficult.

A support interval (SI) has to be used to indicate to which predefined QTL the significant QTL belonged in the simulations. Each predefined QTL was assigned to a predefined interval length centered at the true QTL location, and then the power was determined by counting the number of simulation runs with significant peaks higher than the LOD threshold along the LOD profile in this interval. QTLs not identified in the corresponding SI were viewed as false positives. Five simulated populations from Independent I were used to illustrate how the detection power and FDR were calculated through computer simulation.

When an LOD threshold value of 2.5 was used, IM identified a total of 16 and ICIM identified a total of 20 QTLs in five simulation runs (Table 2). Using the first run as an example, IM did not detect Q1, so its power was 0. One QTL was identified at 25 cM on chromosome 2, but this QTL was not located within the 10 cM SI of the actual position of Q2, i.e., from 30 to 40 cM, and was treated as a false positive. IM identified one QTL at 35 cM, within the 10 cM SI, on chromosome 3, so the detection power for Q3 was 1. The detection power for Q4 was 1 as well, because one QTL was identified on chromosome 4 at 40 cM, within the 10 cM SI of Q4. Across the five runs, the QTLs 1–4 were detected 1, 3, 4, and 5 times, respectively, with SI=10 cM (Table 3). Therefore, the detection powers for the four QTL were 20%, 60%, 80%, and 100%, respectively. In total, there were three false QTLs and 16 positive ones. Therefore, FDR equaled 3/16=19% for IM.

When ICIM was used, the four QTLs were detected 4, 4, 5, and 4 times, respectively (Table 3). Therefore, detection

a) Logarithm of odds; b) phenotypic variance explained by each identified QTL.

powers of ICIM were 80%, 80%, 100%, and 80%, respectively, for the four QTLs. There were a total of three false QTLs and 20 positives. Therefore, FDR of ICIM equaled $3/20=15\%$.

1.4 Position and effect estimates

Precisely locating a QTL's position and estimating its effect are both important in QTL mapping. For a significant QTL

detected by test statistics that exceed a predetermined threshold, the estimate of its genetic effects must be assessed in terms of accuracy and precision. Precision is another criterion by which different statistical methods for QTL detection can be compared, in addition to high power and low FDR. In simulation studies, if the estimates of effect are calculated only from significant QTLs, the effects are usually over-estimated, because simulated QTLs with LOD scores below the threshold may have smaller effects

Table 3 QTL detection frequency and power of interval mapping (IM) and inclusive composite interval mapping (ICIM) estimated from five populations simulated using the Independent I

Method	QTL	Detection times in five runs		Power (%)	
		SI=10 cM	SI=20 cM	SI=10 cM	SI=20 cM
IM	Q1	1	2	20.0	40.0

	False (FDR)	3	2	15.0	10.0

a) False discovery rate.

but will not be counted. Unbiased estimates can be achieved if all runs with peaks are counted, whether or not the peaks are above the LOD threshold.

2 Results

2.1 Power and false discovery rate of IM at a predefined support interval

The QTL detection power of IM was calculated for SI=10 and 20 cM (Table 4). Similar power and FDR were observed for both independent models, indicating that scattering the distribution of favorable and non-favorable alleles between parents had no effect on QTL detection when the QTLs were genetically independent. For the four QTLs considered, those with large genetic effects also had high detection power. For example, Q1 explained only 5% of phenotypic variance, and the power of IM to locate it in the 10 cM SI was 25.8%. In contrast, Q4 explained 20% of phenotypic variance, and the power of IM to locate it in the 10 cM SI was 85.4%.

Linkage significantly reduced detection power and increased FDR (Table 4). Linkage in repulsion (Linkage model II; Table 1) represented the worst case of QTL mapping. Both the LOD score and power were the lowest, and the standard errors of both QTL position and effects were the highest among the four models (Table 4). That larger SI will result in higher power and lower FDR (Tables 3 and 4) is understandable. In this sense, the SI length must be specified when estimating QTL detection power; otherwise, positive and false QTLs cannot be distinguished.

2.2 Power and false discovery rate of ICIM at a predefined support interval

The QTL detection power of ICIM was calculated for SI=10 and 20 cM (Table 5). Almost identical power and FDR were observed for both independent models. QTLs with large

genetic effects also had high detection power. For example, Q1 explained 5% of phenotypic variance, and the power of ICIM to locate it in the 10 cM SI was 49.5%. In contrast, Q4 explained 20% of phenotypic variance, and the power of ICIM to locate it in the 10 cM SI was 89.0%.

Linkage reduced ICIM's detection power and increased FDR (Table 5). Linkage in repulsion (Linkage model II) resulted in the lowest LOD score and power and the highest standard error of QTL position and effects among the four models. For Linkage II, IM had powers of 0.3%, 25.35%, 6.85%, and 40.6% to detect the respective QTLs and FDR=38.8%. In contrast, ICIM had powers 11.65%, 33.05%, 56.25%, and 60.9%, respectively, and FDR=23.8%. In addition, ICIM resulted in smaller standard errors for QTL position and effect.

2.3 Detection power of IM and ICIM on marker intervals

The detection power could be calculated for each interval defined by markers. Power thus determined allows monitoring of QTL locations if not on the putative intervals. For the two independent models, IM and ICIM located QTLs at their flanking intervals in most times. However, there were chances that QTLs were located in other neighboring intervals (Figure 3). For the two linkage models, IM located the two QTLs on chromosome 1 at the middle of the two positions in most times, and so as the two QTL on chromosome 2. ICIM located the two linked QTL on chromosomes 1 and 2 in their flanking intervals in most times, indicating its ability in separating linkage. Generally speaking, linkage complicates the QTL mapping procedure. In other words, much larger population is needed to dissect close linkage.

3 Discussion

Several QTL mapping methods have been developed in the

a) Standard error of estimated position, LOD, or effect; b) logarithm of odds.

www.isbreeding.net). In addition to QTL mapping, the software can build high-density linkage genetic maps as well. The simulation functionality in QTL IciMapping provides a useful tool to compare different mapping methods using a wide range of genetic models.

This work was supported by the National Basic Research Program of China (2011CB100100) and the National Natural Science Foundation of China (31000540).
